Quantum repeater networks

I. QUANTUM REPEATER NETWORKS

CONTENTS

As has been mentioned, any future quantum internet (Kimble, 2008) is going to require the communication of quantum information over arbitrarily long distances. While intercity communication might be implemented via point-to-point connections, intracity and intercontinental communication will require extremely long distance links, well beyond the attenuation length of the optical fibres connecting them. The natural solution to this is to employ quantum repeaters (Gisin and Thew, 2007; Munro *et al.*, 2015; Sangouard *et al.*, 2011) which operate by dividing long-distance links into a finite number of segments interspersed with repeaters (see Fig. 1).

FIG. 1 (a) Schematic representation of an entangled Bell pair $|\Psi\rangle_{A,B}$ shared between remote parties Alice and Bob. The two solid dots represent physical qubits, while the edge represents entanglement. (b) The link may be over a long distance L_{tot}. (c) Due to channel losses the link may be broken into N smaller segments of length L. The links for each of the smaller segments can be independently generated and combined to form the longer distance link.

The links are now over much shorter distances and so can be generated with far higher probability (). Then by stitching these together using entanglement swapping (Sec. ??), we can generate our required long-range entanglement link ().

A. Basic operation

The above description is very hand-wavy, and of course things are a little more complicated in practise. We now examine these ideas in a little more detail, starting with a simple linear chain of repeater stations.

In a quantum repeater network, there are three main operations required ():

1. Entanglement distribution (Sec. I.A.1): to create entangled links between adjacent repeater nodes ().

2. Entanglement purification (Sec. I.A.2): to improve the quality of entanglement between nodes ().

3. Entanglement swapping (Sec. I.A.3): to join adjacent entangled links together to form longer distance links ().

The basic operation of a repeater, as shown in Fig. 2, works as follows:

We begin our preparation of a long-range entangled link by creating multiple entangled pairs between adjacent repeater nodes (the number will depend both on the quality of the pairs we initially generate and also the target quality we want our final pair to have). Once we have enough pairs established between two repeater nodes, we perform entanglement purification, which converts multiple entangled links (pairs) into a fewer number with higher quality. These purification steps, shown in Fig. 2(a-b), are performed on the links between all adjacent repeaters, increasing the quality of the links between those adjacent repeater stations to the required degree. Entanglement swapping, as shown in Fig. 2(c), then creates links twice as long. The resulting entanglement links can then be used for further rounds of purification and swapping until one generates a high quality link between the desired points in the network ().

1. Entanglement distribution

Probably the most important operation for any quantum repeater setup is entanglement distribution, the process of creating entanglement between two remote parties (Alice and Bob) connected by a quantum channel (generally an optical fibre or free-space link). This can be implemented in a number of ways (Sangouard *et al.*, 2011; **?**; **?**; **?**; **?**; **?**; **?**), but can be broadly categorised into three basic schemas:

- Photon emission from the quantum memories in the repeater nodes.

- Photon absorption by the quantum memories.

FIG. 2 Schematic illustration of the basic operation of a quantum repeater network. (a) Preparation of multiple entangled links between adjacent repeater nodes. (b) They are then purified to create higher fidelity links. (c) Entanglement swapping between adjacent pairs creates links of twice the original length. (d) These new links are purified to create higher fidelity ones. (e) Entanglement swapping in creates a link four times the original size. This process continues as necessary to reach target distance and purity.

- Photon emission in one node and absorption in another.

By far, the emission based schemes are the most common, which we concentrate on here. Such schemes operate by using an entanglement process to entangle a quantum memory with a single photon. Ideally one wants to generate a maximally entangled state of the form (Munro *et al.*, 2015),

$$|\Psi\rangle = \frac{1}{\sqrt{2}}(|g\rangle|H\rangle + |e\rangle|V\rangle), \tag{1.1}$$

within the repeater node where $|g\rangle$ and $|e\rangle$ are the two states of the quantum memory, and $|H\rangle$ and $|V\rangle$ are the polarization states of light. The photons from the two repeater nodes (Fig. 3) are then transmitted to a beamsplitter (or PBS in this example). After the PBS the state of the system is,

$$|\Psi\rangle = \frac{1}{2}|g\rangle|g\rangle|H\rangle|H\rangle + \frac{1}{2}|e\rangle|e\rangle|V\rangle|V\rangle$$
$$+ \frac{1}{2}|g\rangle|e\rangle|HV\rangle|0\rangle + \frac{1}{2}|e\rangle|g\rangle|0\rangle|HV\rangle \tag{1.2}$$

One immediately notices that the $|e\rangle|e\rangle$ and $|e\rangle|g\rangle$ contribution are associated with two photons in one of the PBS exit modes, the other being in the vacuum state.
FIG. 3 Entanglement distribution scheme based on quantum emitters and which-path erasure. Each nodes emits a photon entangled with the quantum memories present within that nodes. The photons from the adjacent repeater nodes then interfere on a beamsplitter (or polarising beamsplitter) which erases information about which path the photon took. The photons are then measured in an appropriate basis to project the quantum memories within the nodes onto an entangled state.

However the $|g\rangle|g\rangle$ and $|e\rangle|e\rangle$ terms have one photon in each of the output modes. They are however of opposite polarisation, but measuring those photons in the diagonal/anti-diagonal ($\hat{X}$) basis erases this information yielding an entangled state of the form,

$$|\Psi_\pm\rangle = \frac{1}{\sqrt{2}}(|g\rangle|g\rangle \pm |e\rangle|e\rangle), \tag{1.3}$$

where the sign is given by the parity of the two photodetection outcomes in the $\hat{X}$ basis. This entangled state is stored in the quantum memories between nodes ().

The scheme based on photon absorption by the quantum memories is effectively the time reversal of the emission-based scheme (). Instead of using the beamsplitter to entangle the photons emitted from each memory, an entangled source of photons needs to be used (). Of course, the emission and absorption schemes can be used together in a hybrid architecture.

In any entanglement distribution scheme for quantum networks, the repeater nodes are spatially separated and one must consider channel losses, which are the dominant error source. Channel loss in this situation implies that we do not register a coincidence event between D_1 and D_2, which heralds the entanglement. Thus our entanglement distribution success probability is reduced. In fact, the heralded probability of success can be expressed as (),

$$p_{\text{ED}} = \frac{1}{2}e^{-L/L_0}p_{\text{det}}{}^2, \tag{1.4}$$

where L is the distance between the two repeater nodes with L_0 being the attenuation length of the channel, while p_{det} is the detector efficiency. Here we have ignored the source and coupling efficiencies. It is immediately obvious from this expression that the further the repeater nodes are apart, the lower the probability of success, on an exponentially decaying trajectory. The attenuation length of typical telecom optical fibre is approximately

22.5km and so the average time to generate a distributed entangled pair is,

$$T_{\mathrm{av}} \sim \frac{L}{c \cdot p_{\mathrm{ED}}}$$
$$= \frac{2Le^{L/L_0}}{c \cdot p_{\mathrm{det}}{}^2} \qquad (1.5)$$

where c is the speed of light in the channel. This grows exponentially against node separation and so places important constraints on the lifetime of the quantum memoryies. If we consider pure dephasing effects on our matter qubits, the state of our system can be represented by,

$$\hat{\rho}(F) = F|\Psi_+\rangle\langle\Psi_+| + (1-F)|\Psi_-\rangle\langle\Psi_-|, \qquad (1.6)$$

where F is the fidelity of our entangled state given by,

$$F = \frac{1 + e^{-t/\tau_{\mathrm{D}}}}{2}, \qquad (1.7)$$

with t being the duration over which the entangled state is held in memory, while τ_{D} is the coherence time of the memory. If one only requires a single Bell pair and no further operation are performed, then $t = c/L$. However in a more general setting where multiple pairs are required, the time will be T_{av} on average, which is inversely proportional to the probability of generating the entangled state. The quality of the prepared remote entangled state may therefore not be sufficient for the tasks it is required for due to these finite memory lifetimes or operational gate errors. One needs to be able to purify these entangled resources.

2. Entanglement purification

The finite coherence-time of quantum memories and operational errors caused by quantum gates means some mechanism will be required to improve the fidelity of the distributed entangled state, especially if the spatial separation is large. This is generally achieved by entanglement purification (**????????**) which as it name implies purifies the entanglement to a higher value. The purification operation uses either an error detection code (probabilistic but heralded operations) (**???**) or deterministic error correction codes (**???**). While the error correction codes purify in a deterministic way, they place tough constraints on both the required initial fidelity of entangled states and also the quality of the quantum gates implementing the purification (**?**). Given this, we will focus on the simplest error detection code which requires only a pair of shared entangled quantum memories (as shown in Fig. 4). This scheme is equivalent to the entanglement purification protocol described in Sec. **??**, although the graphical notation is somewhat different.

In this simplest purification protocol, Alice and Bob share two pairs of entangled states of the form given by

FIG. 4 Entanglement purification: (a) The simplest purification scheme involving two pairs of shared remote entangled quantum memories ($A_1 - B_1$ and $A_2 - B_2$). The purification operation begins with Alice performing a CNOT operation between memories A_1 and B_1. Similarly Bob performs a CNOT operation between his memories. Alice and Bob then measure qubits A_2 and B_2 in the computational $(0, 1)$ basis and share their results. They discard the resulting state if between them they measured odd parity $(0, 1$ or $1, 0)$. They keep the state if they measured an even parity between them $(0, 0$ or $1, 1)$ which should have higher fidelity. (b) Two qubits are removed, leaving a residual two-qubit state between A_1 and B_1 with improved fidelity.

Eq. (1.6). These states are a mixture of only two Bell states. We begin our purification protocol by using local operations to transform $\hat{\rho}$ to,

$$\hat{\rho}(F) = F|\Psi_+\rangle\langle\Psi_+| + (1-F)|\Phi_+\rangle\langle\Phi_+|, \qquad (1.8)$$

As shown in Fig. 4 we then apply a CNOT gate between Alice's two memories and Bob's two memories following by measuring A_2, B_2 in the computational basis. Upon measurement of even parity our resulting state $\hat{\rho}(F')$ has the form, but with new fidelity,

$$F' = \frac{F^2}{F^2 + (1-F)^2}. \qquad (1.9)$$

It is immediately obvious that our resulting state $\hat{\rho}(F')$ is more entangled that $\hat{\rho}(F)$ when $F > 1/2$ (see Fig. 5). In fact the degree of entanglement as measured by the concurrence increases from,

$$C = 2F - 1, \qquad (1.10)$$

to,

$$C' = 2F' - 1$$
$$= \frac{2F^2}{F^2 + (1-F)^2} - 1. \qquad (1.11)$$

It is important to mention that the entanglement purification doesn't allow one to distribute a *perfect* Bell state. Rather it *asymptotically* approaches perfection (under ideal conditions) with repetition of the protocol.
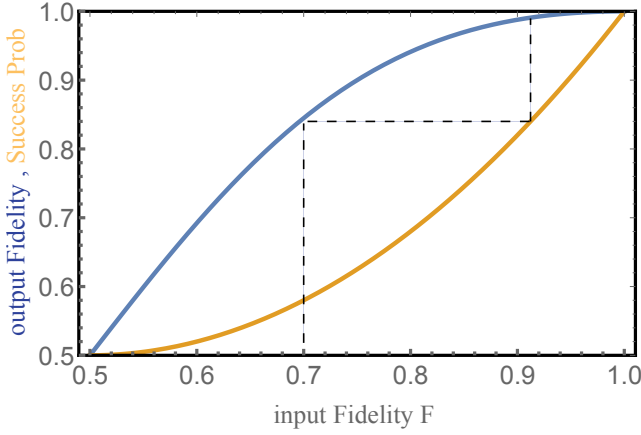

FIG. 5 Plot of the increased fidelity and success probability for entanglement purification for a mixture of two Bell states with initial fidelity F. The dashed lines show how multiple pairs with an initial fidelity $F = 0.7$ can be purified iteratively to a final fidelity above 0.95.

The probability of obtaining the even parity outcome is,

$$p_{\text{even}} = \frac{F^2 + (1 - F)^2}{2}. \qquad (1.12)$$

Alternatively for the odd parity measurement results, which occur with probability,

$$p_{\text{odd}} = F(1 - F), \qquad (1.13)$$

the resulting state is an equal mixture of $|\Psi_+\rangle$ and $|\Phi_+\rangle$ and is not entangled at all. In this case we must start again from scratch with the entanglement distribution.

So far we have discussed one round of entanglement purification but the protocol naturally works in a recursive way where two copies of a state with the same fidelity are used for the next purification round. Using this bootstrapped approach one can in principle generate a near unit fidelity entangled pair from a finite fidelity pair (provided initial input fidelity $F > 1/2$).

There are two common variants of these purification protocols: the Deutsch and Dur variants:

- *Deutsch protocol* (**?**): This is an efficient purification protocol utilising Bell diagonal states that reaches a high fidelity in a few purification rounds. It is assumed that both entangled pairs have the same form. The purification protocol is the same at the one described above in Fig. 4, but begins with Alice (Bob) applying $\pi/2$ ($-\pi/2$) rotations about the X-axis on their qubits before the usual CNOT gates and measurements are performed. Two copies of the successfully purified pair can then be used in a recursive approach to purify either further. This in turns means multiple copies of the originally distributed states are required. We

must have enough entangled pairs available to perform the multiple rounds of purification that are required, which grows exponentially with the number of purification rounds.

- *Dur protocol* (**?**): This uses the same core purification elements shown in Fig. 4 but relaxes the traditional constraint that both Bell pairs must have the same fidelity. Instead we begin with two pairs of the same fidelity F, and perform the traditional purification. If successful we perform the next round of purification using the improved fidelity pair from the previous round and a fresh fidelity F pair. In effect this new auxiliary pair is used to boost the fidelity of the original pair higher. This can continue until we reach a limiting fidelity dependent on the original F. This limiting fidelity may be above the desired resultant fidelity, at which point we can terminate the purification protocol. A significant difference between the Deutsch and Dur protocols is that the number of memories in the Dur situation is linear in the number of nesting levels.

It is critical in repeater protocols to also discuss how fast these purification protocols can be performed. Even with ideal gates one has to wait for the parity information to be shared between the repeater nodes. For nodes separated by a distance L, the communication time for a single trial is L/c. However, remembering that purification is probabilistic but heralded in nature our waiting time could be many multiples of L/c. This will have a dramatic effect on performance, especially if performed at many different stages in the network with increasing distances between nodes.

3. Entanglement swapping

The entanglement distribution and purification scheme discussed previously allow one in principle to create high fidelity entangled states between adjacent repeaters nodes. The next task is to extend the range of our entangled states, and this occurs via simple entanglement swapping (**????**). This was described previously in Sec. **??**, although the notation is modified.

Consider the situation where we have an entangled Bell pairs between nodes A_1 and A_2 and also between B_2 and B_1. The entanglement swapping operation involves a Bell state measurement between the qubits A_2 and B_2 as shown in Fig. 6. After the Bell measurement we have the resultant state,

$$\hat{\rho}_{A_1, A_2}(F) \otimes \hat{\rho}_{B_2, B_1}(F) \rightarrow \hat{\rho}_{A_1, B_1}(F') \qquad (1.14)$$
with,

$$F' = F^2 + (1 - F)^2, \qquad (1.15)$$

FIG. 6 **Smaller labels, others too**Entanglement swapping: (a) An entangled state is shared between Alice and a repeater station ($A_1 - A_2$), and also between the repeater station and Bob ($B_2 - B_1$). The entanglement operation begins by performing a Bell state measurement between A_2 and B_2 using a CNOT gate, and measurements at D_1, D_2. The measurements indicate which Bell state we have projected our state A_1, B_1 onto. (b) The resultant entangled state between A_1, B_1 with the qubits A_2 and B_2 disentangled from it.

where a local correction operation is performed on either A_1 or B_1 depending on the measurement outcome. It is clear that the longer range entangled state $\hat{\rho}_{F'}$ is less entangled that the states $\hat{\rho}_F$ used to generate it. In fact, to first order our fidelity drops from F to F^2. This in turn means that we can not simply purify adjacent repeater pairs and swap them all to create the long range pairs. If we had n links, our final fidelity from all the swapping would scale as F^n. For high fidelity end-to-end entangled links we need to follow the approach outlined in Fig. 2. Finally, depending on how the Bell measurement is implemented, this process could be probabilistic (but heralded) or deterministic in nature. We assign the success probability as p_{ES}.

B. Performance

We now have all the operations required for a repeater to create long-range entanglement. The natural question to ask is how well it performs.

There are several important points to initially consider here. The majority of the repeater operations are probabilistic in nature (entanglement distribution and purification fundamentally, and entanglement swapping dependent upon implementation). While these probabilistic operations may be heralded, classical signalling must be performed between involved nodes to inform them of successes or failures. For entanglement distribution this time is just that associated with the signalling between adjacent nodes. However, purification and swapping are likely to require such signalling over the entire length of the network. This has a dramatic effect on the performance of the repeater network. The normalised rate for generating Bell-pairs over a total distance L_{tot} is given by,

$$R(n, k, L_{\text{tot}}) = \frac{1}{T_{n,k,L_{\text{tot}}} M_{n,k}} \tag{1.16}$$

where $T_{n,k,L_{\text{tot}}}$ is the time to generate a Bell-pair over the total distance using an n-nested repeater configuration with k rounds of purification per nesting level. The distance between repeater nodes is given by,

$$L = \frac{L_{\text{tot}}}{2^n}, \tag{1.17}$$

meaning there are $2^n - 1$ intermediate repeater nodes with Alice and Bob at the endpoints. In Eq. (1.16) we discount our rate by $M_{n,k}$, the total number of quantum memories used. The justification for this is that this provides a fairer comparison when different purification approaches are used. The Deutsch protocol for instance achieves its target fidelity much faster (fewer rounds) than the Dur protocol, but consumes far more resources doing so. **Did I correct this paragraph correctly?**

Now it is straightforward but tedious to show that $T_{n,k,L_{tot}}$ is given by (**?**),

$$
\begin{aligned}
T_{n,k,L_{\text{tot}}} \sim {} & \frac{3^n}{2^{n-1}p_{\text{ED}}} \prod_{i=0}^{n-1} \left(\frac{3}{2}\right)^k \frac{1}{P_{\text{ES}}(n-i)} \prod_{j=0}^{k-1} \frac{1}{p_{\text{P}}(k-j, n-i)} \\
& + \sum_{m=1}^{n} \left(\frac{3^{n-m}}{2^{n-1}}\right) \prod_{i=0}^{n-m} \left(\frac{3}{2}\right)^k \frac{1}{P_{\text{ES}}(n-i)} \prod_{j=0}^{k-1} \frac{1}{p_{\text{P}}(k-j, n-i)} \\
& + \sum_{m=1}^{n} \sum_{q=0}^{k-1} \left(\frac{3^{n-m+q}}{2^{n-2m+q}}\right) \prod_{r=0}^{q} \frac{1}{p_{\text{P}}(k-r, m)} \prod_{i=0}^{n-m-1} \left(\frac{3}{2}\right)^k \frac{1}{P_{\text{ES}}(n-i)} \prod_{j=0}^{k-1} \frac{1}{p_{\text{P}}(k-j, n-i)}
\end{aligned}
$$

where p_{ED} is the probability of successfully distributing entanglement between adjacent repeater nodes, while $p_P(j,i)$ [$p_{ES}(i)$] represents the purification [entanglement swapping] probability at the ith nesting level with j rounds of purification. The factors of $3/2$ present in all entanglement distribution, purification and swapping operations is a multiplicative factor associated with the extra time required for the two pairs to be available for the various quantum operations (Sangouard *et al.*, 2011).

It can be easily seen from this formula that,

$$T_{n,k,L_{\text{tot}}} \gg \frac{2L_{\text{tot}}}{c}, \qquad (1.18)$$

especially if probabilistic gates are included. Next the resources scale polynomially with,

$$M_{n,k} \sim 2^{(k+1)n}$$
$$\sim \left(\frac{L_{\text{tot}}}{L}\right)^{k+1}, \qquad (1.19)$$

for the Deutsch protocol, which in turn implies it is efficient. However for long distances L_{tot}, our normalised rate $R(n,k,L_{\text{tot}}) \ll 1$Hz, especially when probabilistic CNOT gates and Bell state measurements are employed (**??**).

Up to here

C. Second generation repeaters and error correction

The previous approach for entanglement distribution over long distances based on first generation quantum repeaters has it performance heavily constrained by both the probabilistic nature of the various quantum operations and the associated classical communication time. We know that the classical communication in entanglement distribution is only between the adjacent nodes while for the purification and swapping operations it can be large range and may be over the entire network length. This is the fundamental reason why the time to create a pair is of order $O(L_{tot}/c)$ or longer. This will not change significantly even if we have deterministic CNOT gates and Bell states measurements as the entanglement purification protocols will remain being probabilistic in nature (even though the swapping operations will be deterministic). We thus need to replace our usual entanglement purification protocols with a similar operation that is deterministic in nature (**??**).

The typical entanglement purification protocols are a form of quantum error detection code (Munro *et al.*, 2015; **?**). Such codes herald whether an error has occurred or not, and in the situation considered above, the detection of errors means one must discard the entangled pairs associated with the purification protocol. No errors means the purification protocol has worked. Now error correction codes which operate in a deterministic fashion can also detect errors and so can be used in this fashion (**??**). More critically error correction codes have the potential to correct some errors that have occurred. For normal error correction protocols used in quantum computations, one encodes your physical qubits into a logical qubits using the error correcting code and then uses a syndrome measurement to determine where an error has potentially occurred.

Quantum communication however is different in this case as we need to assume that we have generated a number of imperfect Bell pairs between the repeater nodes before we utilise the error correction schemes. The error correction protocol in this case operates by using the error correction encoding circuit on Alice's qubits and the decoding circuit on Bob's (**?**) as is illustrated in Figure **??** for the 5 qubit code (**??**).

It is important to mention here that error correction based purification is deterministic in nature (there is however a significant cost that must be meet - the fidelity of the originally generated between adjacent nodes now has to be quite high) (**??**) . There are no measurement events that need to be discarded. Instead the measurement results only inform you of which particular imperfect Bell state you have and the correction operation required to get you to the particular state you wanted. In effect the measurement is updating you Pauli reference frame (**?**). This does not need to be done immediately and can be delayed until later. In turn this means once, the measurements have been performed, you can immediately use the purified Bell state without having to wait for the classical signaling (at some stage the correction operation needs to be done but this can be when the long distance entanglement has been generated).

The removal of having to wait for the measurement results to be sent and received in both the quantum error correction based purification and also entanglement swapping has a profound effect on the rate of generating long range entangled pairs. One still needs to perform long range classical messaging (potentially between the end nodes). and so it is immediately obvious that the time T can scale solely as $2L_{tot}/c$ which was the lower bound on the first generation schemes (**?**). Naively this seem to imply that the generation rate between the end nodes Alice and Bob can not be faster than this. However one can do very much better! as we illustrate in Fig **??** (and describe in the figure caption). The key issue is that the generation rate depends on how long the adjacent nodes need to keep part of an entangled state within them (**???**).

Fundamentally we know that the time to attempt to generate a single entangled Bell pair between two nodes is scaling as L/c (where L is the distance between those two nodes) and with channel losses we need to make

$$m = \frac{\log_{10} \epsilon}{\log_{10}(1 - p_{ED})} - \log_{10} \epsilon / p_{ED} \qquad (1.20)$$

FIG. 7 **Redo fig** Schematic illustration of a purification circuit based on quantum error correction. The specific example shown is for the [[5,1,3]] code (**??**). In the circuit we assume that entanglement distribution has allowed Alice and Bob to create 5 copies of their imperfect Bell pairs. The error correction circuit is executed independently between the two nodes. While we show the situation when the measurements at both sides are done directly on four pairs of entangled qubits (leaving us with one unencoded Bell pair), one can also use ancilla qubits to measure the appropriate syndromes. As soon as the measurements are complete both nodes qubits are available for continued use as the error correction is deterministic and their are no failure events that need to be heralded. In this case the classical message between nodes just carries Alice?s measurement result allowing either node to interpret which Bell state was generated and for one of them to apply the bit flip or sign flip correction operation if needed to get back to the desired Bell state. In many cases this correction is classically tracked in the Pauli frame (the Pauli frame indicates whether an X, Z or both corrections need to be performed at some time (**??**)). We should also note that it is not necessary to measure out all but one of the qubits involved in the entangled links. Instead the logical qubit can be maintained by the use of ancilla qubits within that node with the syndrome being measured with the help of the ancilla qubits. Entanglement swapping could then be performed on the logical qubits enabling a much more error resilient system.

attempts to generate a single Bell pair with error probability ϵ. We can do this attempts simultaneously and so not affect the generation time. Now by using a butterfly repeater design, as illustrated in Fig **??**, one immediately notices that the qubits with the repeater nodes are only used for a time $2L/c$. After this time those qubits have been freed up and are available to generate new entangled links. This means in turn that the time to generate the long range entangled pair will scale as $T \sim O(2L/c)$ (independent of the overall distance L_{tot}) (**???**). The exacts resources used depends heavily on the error correcting code but we know they in principe scale as M $O(\text{PolyLogL}_{\text{tot}})$ (**?**). This is quite a dramatic decrease in both T and M compared to the first generation. In fact one could expect the normalized rates to be of order $O(kHz)$ (**?**). However this is a significant costs in terms of the quality of the original Bell pairs that one must generate between adjacent nodes. In the generation one schemes a fidelity just over 50 percent was sufficient, however with the second generation schemes using normal error correcting codes, it is likely this initial fidelity will have to be over 90 percent (**??**).

D. Third generation repeaters

The use of error correcting codes has helped in the significance performance improvement available for second generation quantum repeaters. Those second generation schemes are now limited by the communication time between adjacent repeater nodes to herald whether entanglement distribution was successful or not (**??**). The communication (both quantum and classical) is ultimately limited by the speed of light (either in the fiber or free space). The natural question is how we improve the performance further. The only remaining choice is to move from probabilistic to deterministic entanglement distribution. Remembering that we have losses in the channel, the only way to achieve deterministic entanglement distribution will be by transmitting error correctable encoded photon signal between the repeater nodes. This means one must turn to loss based error correction codes (**?????**).

Their are quite a number of error codes that can correct for loss events but here to illustrate how it works we will consider the parity codes in their simplest form (**??**).
FIG. 8 **Redo fig** Schematic illustration of a butterfly design quantum repeater network protocol that reduces the requirements on all the quantum memories times to only that associated with the signaling time between adjacent repeater nodes (**?**). Enough pairs must be generated between the node to ensure that we can use them in the error correction code in a single round trip time between adjacent nodes. The scheme relies multiple entangled pairs being generated temporally starting from the mid point of the network. The protocol begins with the middle or central node creating links to both the left and right nearest neighbor node in sufficient number to allow an error correction code to encoded on the successful pairs. One they are created the error correction circuits are applied to the links left and right of this central node (effectively creating encoded logical links). Entanglement swapping at the middle node is then applied between these logical links creating a logical link between the left and right adjacent nodes. The left and right nodes can then do the same to their next adjacent repeater node, error correcting as they go, until the desired end to end entangled link is achieved.

Consider a four photon state of the form

$$|\Psi\rangle = \quad \alpha \left[|0\rangle_1|0\rangle_2 + |1\rangle_1|1\rangle_2\right] \otimes \left[|0\rangle_3|0\rangle_4 + |1\rangle_3|1\rangle_4\right]$$
$$+ \quad \beta \left[|0\rangle_1|1\rangle_2 + |1\rangle_1|0\rangle_2\right] \otimes \left[|0\rangle_3|1\rangle_4 + |1\rangle_3|0\rangle_4\right]$$
$$(1.21)$$

where $|0\rangle$ and $|1\rangle$ represent orthogonal degrees of freedom (eg polarization). This state can be rewritten in the form

$$|\Psi\rangle = \quad \alpha|\Phi_{12}^+\rangle|\Phi_{34}^+\rangle + \beta|\Psi_{12}^+\rangle|\Psi_{34}^+\rangle \qquad (1.22)$$

where $|\Phi_{ij}^+\rangle = |0\rangle_i|0\rangle_j + |1\rangle_i|1\rangle_j$ and $|\Psi_{ij}^+\rangle = |0\rangle_i|1\rangle_j + |1\rangle_i|0\rangle_j$ and so one observes the state has been encoded into terms of a tensor product of two Bell states (our Bell state are redundantly encoded). Now photon loss will remove one of these photons and for instance, let us consider that photon 4 is lost. The resultant state can be represented by the density matrix $\rho = |\zeta_+\rangle\langle\zeta_+| + |\zeta_-\rangle\langle\zeta_-|$ where

$$|\zeta_+\rangle = \quad \alpha|\Phi_{12}^+\rangle|0\rangle_3 + \beta|\Psi_{12}^+\rangle|1\rangle_3$$
$$|\zeta_-\rangle = \quad \alpha|\Phi_{12}^+\rangle|1\rangle_3 + \beta|\Psi_{12}^+\rangle|0\rangle_3$$

We immediately notice that $|\zeta_-\rangle = X_3|\zeta_+\rangle$ and so by measuring the third photon in the X basis our state reduces to the pure state $\alpha|\Phi_{12}^+\rangle \pm \beta|\Psi_{12}^+\rangle$ with the $\pm$ sign associated with the $X = \pm 1$ result respectively. A simple local operation for the $X = -1$ result transform it to the $X = +1$ case, and so after the loss event of photon 4 and the measurement of the third photon our states becomes

$$\alpha|\Phi_{12}^+\rangle + \beta|\Psi_{12}^+\rangle \qquad (1.23)$$

which has exactly the same information in it as $|\Psi\rangle$ but without the redundancy encoding. It is then straightforward to re-encode back to our original state $\alpha|\Phi_{12}^+\rangle|\Phi_{34}^+\rangle + \beta|\Psi_{12}^+\rangle|\Psi_{34}^+\rangle$. Here we consider photon loss only on the fourth qubit, however it can in principle be any photon that is lost. For this example however the photon loss must be small.

The above example illustrates how the smallest optical loss code work. The general code with $n-1$ redundancy can be written as (**??**)

$$|\Psi\rangle = \quad \alpha|\Phi_e\rangle_1 \ldots |\Phi_e\rangle_n + \beta|\Psi_o\rangle_1 \ldots |\Psi_o\rangle_n \qquad (1.24)$$

where $|\Phi_{e,o}\rangle$ are the even and odd parity m photon states given by

$$|\Phi_{e,o}\rangle = \quad |+\rangle_1 \ldots |+\rangle_m \pm |-\rangle_1 \ldots |-\rangle_m \qquad (1.25)$$

with $|\pm\rangle = |0\rangle \pm |1\rangle$. This redundancy based parity code is composed of n logical qubits each containing m photons. For this code to correct loss errors we have two constraints

- First at least one logical qubit must arrive without photon loss,

- Second, every logical qubit must have at least one photon arriving.

If these constraints are meet, the loss events during transmission between adjacent repeater nodes can be corrected. Of course such codes can not correct more than fifty percent errors and so the distance between repeater nodes is limited. Remembering that the probability of a photon being successfully transmitted through a channel of length L with attenuation length L_0 is given by $p = \exp[-L/L_0]$, the maximum distance between repeater nodes is $L/L_0 \sim 0.69$ (which corresponds to approximately 17Km in commercial telecom fiber). This is much shorter than what we would typically consider the first and second generation schemes.

Let us now describe the operation of the third generation repeater scheme depicted in Figure 9 in detail (??). It begins at the left hand node by Alice encoding her message into a redundancy parity code created on a series of matter qubits using local quantum gates within that repeater node. The quantum state is then transferred/teleported on photons which are transmitted through a lossy channel to the adjacent repeater node. Here two specific operations occur: first the information encoded on each photon is transferred to a matter qubit within that repeater node and then that photon is measured. The photon measurement is critical as it heralds which photons have been lost and allows us to measure the remaining qubit in that block in the X basis. These X basis remove the damaged parity blocks from our redundancy based parity coded state leaving our information intact. We can now add the full redundancy back into our encoded state in the matter qubits. The fully encoded state can then be transferred to photons and transmitted to the next repeater node where the same procedure occurs again. This continues until our state reaches the last repeater node where Bob is. There is one immediate observation that can be made from this scheme. The matter qubits (quantum memories) within the local nodes are only used to encode and error correct the redundancy code as well transmitting those quantum states to photons. Entanglement is not stored within the nodes while the photons are being send to the adjacent repeater nodes. This in turn means the resources within that repeater node can be used immediately again (once the photons have been transmitted) and so the rate of communication is now limited by the time to perform the local operations within a node, rather than the round trip time between adjacent nodes.

The focus so far has been only on loss based errors but this code is fault tolerance to general errors as well (?). Further this redundancy code was only an illustrative example that photon loss in the channel can be corrected. Many other codes can be used in a similar fashion (???). Finally the scheme we have presented in Figure 9 transmits a quantum signal from Alice and Bob. It can however be adapted to use the butterfly design in Figure ?? to create remote entanglement between Alice and Bob while maintaining the performance advantages our direction transmission scheme gave.
FIG. 9 **Redo fig**Schematic illustration of the transmission of a quantum signal using loss based error correction codes in a quantum network.

II. SCALINGS IN THE REPEATER GENERATIONS

As can seen the various quantum repeater generations take quite a different approach to how they distribute entanglement between Alice and Bob over a long distance (**?**). It is useful thus to summarize in Table I the performance of the various repeater approaches and the requirements on them.

Repeater generation	T_{av}	Resources consumed	L_{max}	Local gate precision
First generation	$O(L_{tot}/c)$	$O(\text{poly}(L_{tot}))$	arbitrary	arbitrary
Second generation	$O(2L/c)$	$O(\text{polylog}(L_{tot}))$	arbitrary	high
Third generation	$O(t_{local})$	$O(\text{polylog}(L_{tot}))$	$L/L_0 < 0.69$	fault tolerant levels

TABLE I Quantum repeater approaches and their expected performance scalings. T_{ave} corresponds to the time between which the protocol can be attempted (the time to generate a single Bell state is at least L_{tot}/c) (**?**). The generation rate is $R \sim 1/_{ave}$. Further given are the resources (quantum memories) required as well as the precision for the local gate operations within the repeater node. and L_{max} the maximum spacing between repeater nodes. Within the table L_{tot} is the total distance between Alice and Bob while L is the distance between adjacent repeater nodes. t_{local} is the time required to perform the local operations within the repeater node, while L_0 is the attenuation length of the channel/fiber.

Table I clearly shows that the average time to generate the Bell pair between the end nodes of the repeater network decreases significantly as we move to higher generation quantum repeaters. In the first generation our generation rate is proportional to $O(c/L_{tot})$ which increases to $O(c/L)$ for the second generation schemes and finally to $1/O(t_{local})$ for the third generation ones. The difference here could be more than nine orders of magnitude. Next the number of quantum memories required decreases from $O(\text{Poly}[L_{tot}])$ for the first generation approach to $O(\text{PolyLog}[L_{tot}])$ for the higher ones. The higher generation schemes however come at quite a cost, with the requirement for fully fault tolerance (or near fault tolerance) quantum gates within the repeater node.

In fact it is likely that Alice and Bob will have multiple potential routes between themselves

A. The transition to quantum networks

The previous quantum repeater networks we have discussed have been simple point to point linear networks (Fig 10a). While there were a number fo ways to establish the end to end entangled links between Alice and Bob, they knew they were connected via a simple linear chain. Of course this is highly unrealistic. Alice and Bob are likely to be members of a complex quantum network (Fig 10b) that supports multiple users simultaneously.
FIG. 10 **Redo fig**Schematic illustration of a quantum networks. In a) the typical simple point to point linear quantum repeater network is shown while in b) a more complex topology network is depicted that could in principle support many simultaneous users. The thicker connecting lines represent links between nodes have more capacity.

This leads to a number of interesting considerations going forward.

- First for large scale networks the users may not know it's exact network topology or even the best route between themselves. In fact there could be multiple paths between Alice and Bob. Probing the entire network to establish the best route would be slow and costly (in practical). Still every node should have a unique identifier (quantum ip address) which indicates which part of the network it is part of. .

- Next most complex networks dynamically change in time as resources become congested or nodes break. This in turn means using a butter fly approach to create Alice and Bob's links is problematic as one does not know the middle point between them to start the entanglement creation process. If one has to determine the route in advantage and restrict access to those parts of the network required to

establish the entire links, congestion will quickly follow. The generation rate will be very slow,

- Last it is unlikely that the repeater nodes are equally spatially separated (making the first generation repeater schemes extremely hard to use in this situation).

The above issues leads us to a network model where Alice and Bob suspect there is a route between them but not the exact route (it is llkely to change over time). In such a case if Alice wants to send a message) to Bob, she uses her knowledge of Bob rough location (form the quantum IP address) and her knowledge of the nodes close to her to send a message to a repeater node who will have more knowledge of Bob part of the network. This node can then forward the message to further nodes (who know even more about Bob location) until it finally reaches Bob. The quantum ip address is essential here as that identifier indicates to the repeater node who to forward to next. In principle as the message (or entanglement) is being established node by node, those repeater nodes who have already been used are free to work for tasks for other users.

There is another interesting aspect of our general complex quantum networks. There are likely to be many paths between Alice and Bob which could be attempted in superposition fashion. This will not only increase the capacity between Alice and Bob but also it robustness.
